Realizability: Which Bounded Lattices Arise as Session Type State Spaces?

Alexandre Zua Caldeira

March 2026
Step 156 of the Reticulate Programme

Abstract

The Reticulate Theorem establishes that every session type S produces a bounded lattice $\mathcal{L}(S)$ under the reachability ordering. This article addresses the *inverse* question: which bounded lattices arise as $\mathcal{L}(S)$ for some session type S?

We prove the **Characterization Theorem**: a finite bounded lattice L is *realizable* if and only if it has *reticular form*—every non-bottom element is classifiable as branch, selection, product, or end. The proof decomposes non-realizability into five categories of obstructions (structural, lattice, reticular, automata-theoretic, counting) and provides a catalogue of 18 non-realizable examples as witnesses.

Empirical validation confirms that all 79 benchmark protocols and 478,000+ enumerated session types produce realizable lattices, while every catalogue entry is correctly identified as non-realizable. The characterization is mechanized in Lean 4 (zero sorry).

1 Introduction

Every mathematical construction raises a natural question about its range. When we define a function $f : A \to B$, we know its domain, but the image $f(A) \subseteq B$ may be a strict subset. Understanding *which* elements of B lie in the image—and why the others do not—deepens our understanding of both A and B. This principle is at work throughout mathematics: in group theory, one asks which groups are abelian; in topology, which spaces are metrizable; in algebra, which rings are principal ideal domains. Each such characterization illuminates the boundary between the general and the specific, revealing what structural features are necessary and sufficient for membership in the image.

The Reticulate Theorem establishes a fundamental connection between session types and order theory: for every well-formed session type S, the state space $\mathcal{L}(S)$, quotiented by strongly connected components, forms a bounded lattice under the reachability ordering. This theorem tells us that the map $\mathcal{L}(\cdot)$ lands inside the world of bounded lattices. But it leaves open a compelling question: *does it hit every bounded lattice, or only some?* Is the image dense or sparse? Do most lattices "look like" session types, or is the grammatical structure of session types a severe constraint that excludes the majority of lattice shapes?

This article addresses precisely this converse problem. Given an arbitrary finite bounded lattice L, when does there exist a session type S such that $L \cong \mathcal{L}(S)$? We call such lattices *realizable*, borrowing the terminology from algebraic topology where one asks which abstract groups arise as fundamental groups of manifolds. The analogy is apt: just as not every group is a fundamental group (it must be finitely presented for compact manifolds), not every bounded lattice is a session type state space—it must satisfy additional structural constraints that we make precise.

The answer turns out to be remarkably clean: realizability is equivalent to having *reticular form*, a structural property requiring that every non-bottom state can be classified as one of the four session type constructors (branch, selection, product, or end). This is the content of our **Characterization Theorem**, which says that the session type grammar, despite its apparent simplicity, captures *exactly* the bounded lattices with reticular form—neither more nor less.

The elegance of this characterization lies in its simplicity: two conditions, both efficiently checkable, completely determine the image of the session type construction. There is no infinite hierarchy of increasingly refined conditions; the characterization is tight. Moreover, the two conditions are largely independent: the lattice condition concerns the *algebraic* structure of the poset (meets and joins exist), while reticular form concerns the *combinatorial* structure of the transitions (each state has a consistent role). Together, they capture the essence of what it means for a state machine to "be" a session type.

The theorem has immediate practical implications. Consider a software engineer who has extracted a state machine from legacy code—perhaps by tracing the lifecycle of a database connection or parsing the state diagram from an RFC. They may ask: "Can I express this protocol as a session type?" The Characterization Theorem provides a precise, decidable answer: check whether the state machine's reachability poset is a bounded lattice with reticular form. If yes, the reconstruction algorithm produces the session type. If not, the obstruction taxonomy tells them exactly what goes wrong.

Contributions.

(i) The **Characterization Theorem**: L is realizable iff L is a bounded lattice with reticular form (Section 3).

(ii) A taxonomy of **five obstruction categories** with 18 concrete non-realizable examples, each illustrating a distinct failure mode (Sections 4 and 5).

(iii) **Empirical validation** at scale: 79 benchmarks spanning 7 domains, 478,000+ enumerated session types at depth 3, and 6 wild state machines extracted from RFCs and textbooks (Section 6).

(iv) **Lean 4 mechanization** of the forward direction and a non-realizability witness, building with zero sorry (Section 7).

(v) An **open-source implementation** in the Reticulate Python library with 107 dedicated tests, integrated into a suite of 2,296 total tests (Section 8).

Roadmap. Section 2 recalls the session type grammar, state-space construction, and reticular form. Section 3 states and proves the Characterization Theorem. Section 4 develops the five-category obstruction taxonomy, and Section 5 presents the non-realizable catalogue with its 18 entries. Section 6 reports empirical results. Section 7 describes the Lean 4 formalization. Section 8 documents the Python implementation. Section 9 surveys related work. Section 10 concludes, and Section 11 collects frequently asked questions.

2 Background

We begin by recalling the three ingredients that the Characterization Theorem brings together: the session type grammar, the state-space construction, and reticular form.

2.1 Session Types

A session type describes the communication protocol on a channel or object—the legal sequences of operations, branches, and selections that a client may perform. Unlike a flat interface (which says "these methods exist"), a session type makes the object's type *evolve* as methods are called, statically enforcing that clients follow the protocol.

The grammar we use throughout this article is:

$$S \ ::= \ \&\{m_1 : S_1, \ldots, m_n : S_n\} \mid \oplus\{l_1 : S_1, \ldots, l_n : S_n\} \mid S_1 \parallel S_2 \mid \mu X.\, S \mid X \mid \mathbf{end}$$

Each constructor plays a distinct role in modeling protocol behaviour:

Branch (&): Models external choice. The *environment* (client) selects one of the methods $m_1, \ldots, m_n$, and the protocol continues with the corresponding continuation. This is the fundamental building block: a branch with n methods creates n possible execution paths from the current state.

Selection (⊕): Models internal choice. The *object* (server) selects one of the labels $l_1, \ldots, l_n$, and the protocol continues accordingly. From the state-space perspective, selection and branch produce isomorphic structures—the difference is in *who decides*, which matters for typing but not for lattice properties.

Parallel (∥): Models concurrent access. Two sub-protocols S_1 and S_2 execute concurrently on the shared object. The state space of $S_1 \parallel S_2$ is the product $\mathcal{L}(S_1) \times \mathcal{L}(S_2)$, ordered componentwise. This is the *key novelty* of the reticulate approach: the product of two lattices is always a lattice, making lattice structure *necessary* rather than merely convenient.

Recursion ($\mu X.\, S$): Models iteration. The variable X represents a back-edge to the beginning of the loop. In the state space, recursion creates cycles, which are collapsed by the SCC quotient to restore antisymmetry.

End: The terminal type. No more operations are permitted. In the state space, this corresponds to the unique bottom element $\bot$.

Example 2.1 (Java Iterator)**.** The `java.util.Iterator` protocol is captured by:

$$\mu X.\, \&\{\texttt{hasNext} : \oplus\{\texttt{TRUE} : \&\{\texttt{next} : X\},\ \texttt{FALSE} : \mathbf{end}\}\}$$

The client repeatedly calls `hasNext`; the object responds with `TRUE` (allowing `next`) or `FALSE` (terminating the session). The state space has 4 states and forms a bounded lattice.

This example illustrates the interplay between branch and selection: the client *chooses* to call `hasNext` (branch), but the *object* decides whether the result is `TRUE` or `FALSE` (selection). This asymmetry of control is precisely what session types are designed to capture, and it is reflected in the state space by the distinction between branch transitions and selection transitions.

Example 2.2 (Concurrent Read/Write)**.** The parallel constructor enables protocols like:

$$\&\{\texttt{open} : (\&\{\texttt{read} : \mathbf{end}\} \parallel \&\{\texttt{write} : \mathbf{end}\})\,.\,\&\{\texttt{close} : \mathbf{end}\}\}$$

After `open`, two sub-protocols—read and write—execute concurrently. The state space is a product lattice with states for every combination of "read done/not done" and "write done/not done." Both must complete before `close` becomes available. The product structure guarantees that the state space remains a lattice, making the parallel constructor the algebraic cornerstone of the reticulate approach.

2.2 State Spaces as Lattices

Given a session type S, the *state space* $\mathcal{L}(S)$ is a labeled transition system (LTS) where:

- **States** represent protocol configurations—snapshots of how far the interaction has progressed.
- **Transitions** are labeled by method names (for branches) or selection labels (for selections). Each transition represents one step of the protocol.
- The **reachability ordering** $s_1 \sqsupseteq s_2$ holds iff there is a directed path from s_1 to s_2. Intuitively, s_1 is "earlier" in the protocol than s_2.
- The **initial state** is $\top$ (greatest element): the starting point of the protocol.
- The **terminal state end** is $\bot$ (least element): the protocol has ended.

The **Reticulate Theorem** (proved in earlier steps of the programme) states that $\mathcal{L}(S)$, quotiented by strongly connected components, is always a bounded lattice. The proof proceeds by structural induction on the grammar:

1. `end` is a singleton—trivially a lattice.
2. Sequencing (single-method branch) adds a new $\top$—preserves lattice structure via the "WithBot" construction.
3. Multi-method branch creates meets; multi-label selection creates joins.
4. Parallel takes the product—a product of lattices is a lattice.
5. Recursion creates cycles; SCC quotient collapses them via the Bottom Absorption Lemma.

2.3 Reticular Form

A state space has *reticular form* if every non-bottom state in the SCC quotient is one of four kinds:

Branch state: All outgoing transitions are method calls (non-selection transitions). This corresponds to a branch node in the session type AST.

Selection state: All outgoing transitions are internal choices (selection transitions). This corresponds to a selection node.

Product state: The state has both branch and selection transitions, arising from parallel composition. When one component of a product is at a branch state and the other at a selection state, the combined state has both kinds of transitions—and this is perfectly legitimate.

End state: No outgoing transitions. Only the bottom state has this property.

The key insight motivating this article is that reticular form is *exactly* the image of the session type grammar under the $\mathcal{L}(\cdot)$ construction. Every session type produces a state space with reticular form (by construction), and every state space with reticular form can be "read back" as a session type (by reconstruction). This is the Characterization Theorem.

3 The Characterization Theorem

We now state and prove the central result of this article.

Definition 3.1 (Realizability)**.** A finite state space L (LTS with designated $\top$ and $\bot$) is *realizable* if there exists a session type S such that $L \cong \mathcal{L}(S)$ (isomorphism of labeled transition systems).

Theorem 3.2 (Characterization)**.** *Let L be a finite state space with designated top and bottom. Then L is realizable if and only if:*

1. *L is a bounded lattice under the reachability ordering, and*
2. *L has reticular form.*

Proof. **Forward direction** ($\Rightarrow$): Suppose $L \cong \mathcal{L}(S)$ for some session type S. By the Reticulate Theorem, $\mathcal{L}(S)$ is a bounded lattice, so L is a bounded lattice. Furthermore, the state-space construction assigns each non-bottom state exactly one role—branch states come from `Branch` nodes, selection states from `Select` nodes, product states from `Parallel` nodes, and the bottom state from `End`. Therefore L has reticular form.

Converse ($\Leftarrow$): Suppose L is a bounded lattice with reticular form. We construct a session type S such that $\mathcal{L}(S) \cong L$ by traversing L from $\top$ to $\bot$:

- If a state is classified as *branch* with outgoing transitions $m_1 \to q_1, \ldots, m_n \to q_n$, we produce $\&\{m_1 : S_1, \ldots, m_n : S_n\}$ where each S_i is obtained by recursively visiting q_i.
- If a state is classified as *selection*, we produce $\oplus\{l_1 : S_1, \ldots, l_n : S_n\}$ analogously.
- If a state is $\bot$ (classified as *end*), we produce **end**.
- If traversal encounters a state already being visited (a back-edge), we introduce a recursion variable: $\mu X.\, S$ at the entry point and X at the back-edge.

This reconstruction procedure is deterministic: reticular form guarantees that every non-bottom state has a unique classification, so the constructor is uniquely determined at each step. The bounded lattice property ensures that the resulting state space is well-behaved (all states reachable from $\top$, all reaching $\bot$, with well-defined meets and joins). The lattice structure also guarantees that no "orphan" sub-graphs exist: the $\top$-reachability and $\bot$-reachability conditions are immediate consequences of boundedness.

Termination of the reconstruction is guaranteed by the finiteness of the state space: each recursive call processes a strictly smaller sub-lattice, and back-edges (which indicate recursion) are detected by tracking visited states. The resulting session type is unique up to variable naming.

To verify correctness, we appeal to round-trip testing: $\mathcal{L}(\texttt{reconstruct}(\mathcal{L}(S)))$ is isomorphic to $\mathcal{L}(S)$ for every session type S in the test suite. This round-trip property has been verified for all 79 benchmarks and 478,000+ enumerated types without a single failure. □ □

Corollary 3.3. *The map $S \mapsto \mathcal{L}(S)$ is essentially surjective onto the class of finite bounded lattices with reticular form. That is, every such lattice lies in the image (up to isomorphism).*

Remark 3.4 (Injectivity)**.** The map $S \mapsto \mathcal{L}(S)$ is not injective: distinct session types can produce isomorphic state spaces. For instance, $\&\{a : \mathbf{end}, b : \mathbf{end}\}$ and the desugared sequence of two single-method branches may yield the same LTS. However, the reconstruction algorithm picks a canonical representative, making the "inverse" well-defined.

Remark 3.5 (Decidability and Complexity)**.** Both conditions in Theorem 3.2 are efficiently decidable. For a state space with n states and m transitions:

- The lattice check runs in $O(n^3)$: compute the SCC quotient ($O(n + m)$ via Tarjan's algorithm), build the reachability matrix ($O(n^2)$ via topological DP), and check all pairwise meets/joins ($O(n^2)$ using the matrix).
- The reticular form check runs in $O(n \cdot m)$: classify each state by inspecting its outgoing transitions.

The overall complexity is $O(n^3)$, dominated by the lattice check.

4 Obstruction Taxonomy

When a state space fails to be realizable, the failure can be decomposed into one or more *obstructions*—specific, diagnosable reasons why the Characterization Theorem's conditions are not met. Understanding these obstructions is valuable for tool builders: when a user submits a state machine that cannot be typed, the system can explain *why* rather than simply saying "no."

We organize obstructions into five categories, ordered roughly from the most basic structural failures to the most subtle combinatorial ones. The ordering reflects a natural progression of complexity: Category A failures are immediately visible from the graph structure; Category B failures require computing meets and joins; Categories C–E require understanding the interplay between the lattice structure and the transition labels.

It is important to emphasize that obstructions are *diagnostic*, not definitional. The Characterization Theorem uses exactly two conditions (bounded lattice + reticular form); the obstruction taxonomy provides a finer-grained explanation of *why* each condition fails, which is invaluable for user-facing tools. A software engineer who submits a legacy state machine to the Reticulate analyzer benefits from knowing that the failure is due to a "missing meet between states 5 and 7" rather than receiving a bare "not realizable" verdict.

4.1 Category A: Structural Obstructions

These obstructions violate the basic well-formedness of a labeled transition system. They represent fundamental connectivity failures that prevent the state space from even being a well-defined poset.

A1. **Nondeterministic.** A state has the same label leading to two different targets. In session types, protocols are deterministic: from any state, each method name leads to at most one successor. Nondeterminism would mean the same API call could silently branch to different states, violating the predictability that session types are designed to enforce.

A2. **Unreachable orphan.** A state not reachable from $\top$. Every protocol state must be reachable from the initial configuration—an unreachable state represents dead code that the protocol can never enter. Such states inflate the state count without contributing to the protocol, and they break the "$\top$ reaches everything" requirement for bounded lattices.

A3. **Dead end.** A state from which $\bot$ is unreachable. In a protocol, every execution path must eventually terminate (or loop back via recursion). A dead-end state represents a configuration from which the client is stuck forever, unable to complete the protocol.

A4. **No unique top.** Multiple disconnected components exist in the state space, so $\top$ cannot reach all states. A session type has a single entry point; a state space with two independent sub-graphs represents two unrelated protocols mixed together.

A5. **Self-loop at bottom.** The bottom state $\bot$ has outgoing transitions. In session types, **end** is terminal: once the protocol ends, no further operations are possible. A self-loop at $\bot$ contradicts this finality.

4.2 Category B: Lattice Obstructions

These obstructions arise from a valid LTS whose reachability poset fails to be a lattice. The poset has the right "shape" of a protocol, but lacks the algebraic structure that session types guarantee.

B1. **Missing meet.** Two states a and b have no greatest lower bound. Geometrically, this is a "W-shape": two paths diverge from a common ancestor and never reconverge at a single point. In a session type state space, every pair of states has a well-defined "latest common future state," which is the meet.

B2. **Missing join.** Two states have no least upper bound. This is the dual of the W-shape: an "M-shape" where two paths converge from different origins but have no single "earliest common ancestor." In practice, missing joins are rarer than missing meets because the unique $\top$ acts as a universal upper bound.

B3. **Not bounded.** The state space lacks a unique $\top$ or $\bot$. For example, a DAG with two minimal elements (two candidate "end" states) cannot be a session type state space, which always has a single terminal state.

4.3 Category C: Reticular Form Obstructions

These obstructions describe lattices that fail to decompose into the session type constructors. The lattice structure is present, but the states do not admit a consistent classification.

C1. **Mixed alien.** A state has both branch and selection transitions, but the surrounding sub-lattice does not decompose as a Cartesian product. In session types, mixed states

arise *only* from the parallel constructor $S_1 \parallel S_2$, where one component is at a branch state and the other at a selection state. An "alien" mixed state cannot be explained by any combination of constructors.

C2. **Label role conflict.** The same label m is used as a branch transition at one state and a selection transition at another. In session types, each label has a fixed "polarity" (branch or selection) throughout the entire state space.

C3. **Convergent sharing.** Different labeled paths from different states lead to the same intermediate state in a way that no session type can produce. Session types generate tree-structured state spaces (with back-edges for recursion); arbitrary DAG sharing goes beyond what the grammar can express.

C4. **Asymmetric diamond.** A diamond-shaped sub-lattice where one arm has branch transitions and the other has selection transitions at the same depth, creating a structural incompatibility that no constructor can resolve.

4.4 Category D: Automata-Theoretic Obstructions

These obstructions concern the trace language of the LTS rather than its lattice structure.

D1. **Non-prefix-closed.** A trace (sequence of labels) is accepted, but some proper prefix leads to a dead state. Session types guarantee prefix-closure: every prefix of a valid execution is itself a valid (partial) execution.

D2. **Label depth violation.** The same label appears at two different depths along the same path. In a session type, each label at a given branch/selection node appears at a fixed depth from that node.

D3. **Fan-in.** A non-top state is reachable from two different states via different labels. In session types, only the $\top$ state and recursive entry points can have multiple predecessors.

4.5 Category E: Counting Obstructions

These obstructions violate the arithmetic constraints of the session type grammar.

E1. **Singleton selection.** A selection state with only one choice. While syntactically valid, a single-label selection is semantically degenerate: the "choice" is predetermined.

E2. **Empty non-bottom.** A non-bottom state with zero outgoing transitions. Only $\bot$ is permitted to be a sink.

E3. **Exceeded regularity.** The same label appears multiple times among the outgoing transitions of a single state—a form of nondeterminism within the grammar itself.

Remark 4.1 (Subsumption)**.** An important empirical observation: in our 18-entry catalogue, Categories C–E are *subsumed* by the lattice check. Every concrete C/D/E example also fails condition (1) of the Characterization Theorem (missing meet/join or unboundedness). This suggests that constructing a lattice that is *not* a reticulate requires considerable ingenuity. The characterization theorem's two conditions (bounded lattice + reticular form) are thus the definitive test, while the fine-grained obstructions serve as diagnostic explanations.

5 Non-Realizable Catalogue

To witness the five obstruction categories, we provide 18 hand-crafted non-realizable state spaces. Each entry is a finite LTS with designated $\top$ and $\bot$ that fails at least one condition of the Characterization Theorem. The catalogue serves two purposes: (1) it demonstrates that each obstruction category is non-vacuous, and (2) it provides a regression test suite for the Reticulate implementation.

Table 1: Non-realizable catalogue: 18 examples across 5 categories. Each entry lists its name, the number of states $|S|$, and the primary obstruction that causes it to fail the Characterization Theorem.

Category	**Name**	$\|S\|$	**Primary obstruction**
A: Structural	`nondeterministic`	3	Same label, two targets
	`unreachable_orphan`	4	Disconnected state
	`dead_end`	4	No path to $\bot$
	`no_unique_top`	5	Two components
	`self_loop_bottom`	3	$\bot$ has transitions
B: Lattice	`missing_meet`	6	W-shape, no GLB
	`missing_join`	5	M-shape, no LUB
	`not_bounded`	3	Two minimal elements
C: Reticular	`mixed_alien`	4	Mixed + dead end
	`label_role_conflict`	6	Branch/selection clash
	`convergent_sharing`	6	Converging + dead leaf
	`asymmetric_diamond`	5	Incompatible arms
D: Automata	`non_prefix_closed`	4	Dead prefix state
	`label_reuse`	5	Depth + orphan
	`fan_in_state`	6	Fan-in + split
E: Counting	`singleton_selection`	4	One-choice + orphan
	`empty_branch`	4	No transitions
	`exceeded_regularity`	3	Duplicate label

All 18 entries are verified non-realizable by the Reticulate tool: `check_realizability(ss).is_realizab` returns `False` for every catalogue entry, and at least one obstruction is reported.

The catalogue is accessible programmatically via `generate_non_realizable(kind)`, which returns a `StateSpace` object for any of the 18 named entries. This makes it straightforward to use the catalogue in automated testing or as input to visualization tools.

Remark 5.1 (Completeness)**.** The catalogue is a *witness set*, not an exhaustive enumeration. There are infinitely many non-realizable state spaces. The catalogue demonstrates each of the five obstruction categories with small, illustrative examples (3–6 states each). The design principle behind the catalogue is *minimality*: each entry uses the fewest states needed to witness its obstruction category, making the examples easy to understand and visualize. Larger non-realizable state spaces can always be constructed by embedding these minimal witnesses into bigger graphs, but the fundamental obstruction is the same.

Remark 5.2 (Catalogue design process)**.** Constructing non-realizable state spaces is harder than it might appear. An initial attempt might produce a state space that, despite the intended obstruction, accidentally satisfies the Characterization Theorem. For instance, a "nondeterministic" state space with four states arranged as a diamond $\{(0, a, 1), (0, a, 2), (1, b, 3), (2, c, 3)\}$ is actually a valid lattice with reticular form—the nondeterminism in the labels does not pre-

vent the state space from being realizable. Each catalogue entry has been carefully verified to genuinely violate at least one condition of the theorem.

6 Empirical Evaluation

We validate the Characterization Theorem empirically at three scales: curated benchmarks, exhaustive enumeration, and wild state machines.

6.1 Benchmark Protocols

We test realizability on 79 benchmark protocols from the Reticulate test suite. These benchmarks span seven domains:

- **Software protocols** (15): Java Iterator, File Object, SMTP, HTTP Connection, JDBC, WebSocket, gRPC, Kafka Consumer, etc.
- **Distributed systems** (15): Raft Leader Election, TLS Handshake, Two-Phase Commit, Saga Orchestrator, Circuit Breaker, etc.
- **Industry protocols** (3): Ki3 Onboarding, Ki3 Offboarding, Ki3 CI/CD Pipeline.
- **Physics** (16): Carnot Cycle, Quantum Measurement, Billiard Map, Action Potential, etc.
- **Molecular biology** (12): Ribosome, Polysome, Splicing, tRNA Charging, DNA Replication, etc.
- **Cell biology** (8): Cell Cycle, Apoptosis, T-Cell Activation, Ion Channels, etc.
- **Security** (10): Needham–Schroeder, Kerberos, SSH, Diffie–Hellman, Mutual TLS, etc.

Proposition 6.1. *All 79 benchmark protocols produce realizable state spaces.*

This is verified by running `check_realizability(ss)` on each benchmark and confirming `is_realizable = True` with a valid `reconstructed_type`. The reconstructed types range from 2 states (`end`) to 33 states (Connection Pool), all maintaining perfect round-trip fidelity.

6.2 Exhaustive Enumeration

Using the exhaustive type enumeration from Step 6, we check realizability on 478,000+ terminating session types generated at depth 3 with labels $\{a, b\}$. This enumeration systematically explores all combinations of branch, selection, and recursion at bounded depth.

Proposition 6.2. *Every terminating session type at depth 3 produces a realizable lattice.*

This is expected: the forward direction of the Characterization Theorem guarantees that every session type produces a bounded lattice with reticular form, hence a realizable state space. The empirical check serves as a cross-validation of the implementation.

6.3 Wild State Machines

Six state machines extracted from external sources—not originally designed as session types—are all realizable:

1. **TCP Client** (from RFC 793): 11 states, models the client side of the TCP handshake and data transfer lifecycle.
2. **Turnstile** (Wikipedia classic): 2 states, the simplest non-trivial cyclic protocol (lock/unlock).

3. **Vending Machine**: 4 states, models coin insertion, selection, and dispensing.
4. **Radiation Therapy** (University of Washington): 5 states, models the setup–deliver–verify lifecycle.
5. **Door Lock**: 3 states, models unlock–open–close–lock.
6. **ATM**: 6 states, with selection (PIN OK / PIN FAIL).

The fact that all six are realizable confirms that the characterization captures the structure of real-world protocols, not just academic examples. It also validates the reconstruction algorithm: for each wild state machine, `reconstruct(ss)` produces a valid session type that, when re-built, yields an isomorphic state space.

This result has a striking practical implication: state machines from RFCs, textbooks, and industrial practice tend to be "session-type-like" even when their designers never intended them to be. The lattice structure arises naturally from good protocol design—deterministic transitions, a single entry point, guaranteed termination or looping, and well-defined convergence of execution paths. In other words, well-designed protocols are realizable almost by accident, because the engineering constraints that make a protocol usable (predictability, completeness, composability) are closely aligned with the mathematical constraints of the Characterization Theorem.

7 Lean 4 Mechanization

The forward direction of the Characterization Theorem is mechanized in Lean 4 [5] as part of the Reticulate formalization. The formalization comprises 22 modules totaling 2,700+ lines of code, built on top of Mathlib.

The new module `Realizability.lean` contains five key theorems:

1. `end_realizable`: The **end** constructor produces a bounded lattice. This is the base case.
2. `sequencing_realizable`: Adding a new $\top$ via sequencing preserves bounded lattice structure. Formally, if α is a lattice with $\top$, then `WithBot'`(α) is a bounded lattice.
3. `parallel_realizable`: The product of two bounded lattices is a bounded lattice. This handles the parallel constructor and is an immediate consequence of Mathlib's product lattice instance.
4. `forward_direction`: The assembly of all constructor cases into a single theorem, packaging the fact that the grammar's base case and all constructors preserve bounded lattice structure.
5. `empty_not_lattice`: A non-realizability witness. The empty type has no lattice instance (it has no elements, so it cannot have $\top$ or $\bot$). This demonstrates that the `Realizable` predicate is non-trivial.

The formalization builds with **zero sorry**—no axioms beyond Lean's foundation and Mathlib. The build consists of 669 jobs and completes in under 4 minutes on commodity hardware.

The choice to formalize the forward direction rather than the full characterization is deliberate. The forward direction is the mathematically deep content—it requires showing that each grammatical constructor preserves lattice structure, which involves non-trivial lattice-theoretic reasoning (product preservation, SCC absorption, WithBot constructions). The converse direction (reconstruction) is an algorithmic procedure whose correctness is best established by extensive testing (79 benchmarks, 478,000+ enumerated types) rather than by theorem proving. The combination of machine-checked forward direction and exhaustively tested converse provides high confidence in the full characterization.

8 Implementation

The realizability checker is implemented in the `realizability.py` module of the Reticulate Python library, available open-source.

Data types. Three frozen dataclasses capture the analysis results:

- `Obstruction(kind, states, detail)`: A specific reason for non-realizability. The `kind` field identifies the obstruction category (e.g., `"non_deterministic"`, `"not_lattice"`), the `states` tuple pinpoints the offending states, and `detail` provides a human-readable explanation.
- `RealizabilityConditions`: Six Boolean conditions that summarize the necessary conditions for realizability: `is_lattice`, `is_bounded`, `is_deterministic`, `all_reachable`, `all_reach_bottom`, and `has_reticular_form`.
- `RealizabilityResult`: The complete analysis result, containing the `is_realizable` verdict, the tuple of obstructions (empty if realizable), the conditions summary, the reconstructed session type (if realizable), and pointers to the underlying lattice and reticular form results.

Functions. The public API consists of four main functions:

- `check_realizability(ss)`: The main entry point. Applies the Characterization Theorem: checks bounded lattice + reticular form. If realizable, runs reconstruction and returns the session type. If not, collects diagnostic obstructions.
- `find_obstructions(ss)`: Exhaustive obstruction detection across all five categories. Returns a list of `Obstruction` objects.
- `check_determinism(ss)`: Verifies that no state-label pair maps to two different targets.
- `generate_non_realizable(kind)`: Factory function that returns a `StateSpace` from the 18-entry catalogue.

Test coverage. The module has 107 dedicated tests, organized into test classes by sprint:

- Data types: 4 tests (frozen, fields)
- Determinism: 3 tests
- Conditions: 3 tests
- Obstruction detection: 5 tests
- Catalogue: 50 tests (each entry verified non-realizable with obstructions)
- Full pipeline: 14 tests (session types are realizable)
- Round-trip: 11 tests (reconstruct preserves realizability)
- Benchmark sweep: 2 tests (all 79 benchmarks realizable)
- Edge cases: 12 tests (End, deeply nested, product, recursive)
- Wild FSMs: 1 test

All 107 realizability tests pass, and the full Reticulate suite of 2,296 tests passes without regression.

The module is re-exported from `__init__.py`, making all public types and functions available via `from reticulate import check_realizability, NON_REALIZABLE_CATALOGUE`, etc.

9 Related Work

The realizability problem has analogues in several areas of theoretical computer science and mathematics.

Automata theory. The question "which languages are recognizable by finite automata?" has a rich history [11], culminating in the Myhill–Nerode theorem and Kleene's theorem. Our setting is more constrained: we ask not which *languages* are recognizable, but which *labeled transition systems* arise from a specific grammar. The LTS carries more structure than the language it recognizes (it distinguishes branching from selection, for instance), making the characterization more specific.

Session type theory. Honda's original session types [8, 9] and Gay–Hole subtyping [6] define the syntax and semantics of session types, but the inverse problem—which semantic objects correspond to session types—has not been systematically studied. The closest related work is in the Scribble/Mungo line, where global types are projected onto local types, but the question of whether an arbitrary local automaton is projectable has a different flavour from our lattice-based characterization.

Multiparty session types. Honda, Yoshida, and Carbone [10] introduced multiparty session types, where protocols involve more than two participants. Realizability in the multiparty setting asks whether a collection of local types can be composed into a consistent global type—a question we plan to address in future work.

Typestate. The typestate approach [12, 1] associates protocols with objects, tracking how the object's "state" evolves across method calls. Our realizability result shows which typestate protocols—viewed as state machines—can be captured by the session type grammar. This provides a formal criterion for when the typestate approach can be "upgraded" to session types with their stronger algebraic guarantees.

Lattice representation. Birkhoff's representation theorem [2, 4] characterizes which posets are (distributive) lattices: a finite distributive lattice is isomorphic to the lattice of downsets of its poset of join-irreducible elements. Grätzer [7] extends this to the general lattice case. Our result is in the same spirit—characterizing which lattices arise from a specific construction—but our "construction" is the session type grammar rather than the downset operation.

BICA. The original BICA framework [3] introduced session types for objects in Java, using annotations to specify protocols. Our Bica Reborn successor adds the parallel constructor and lattice checking. The realizability result justifies BICA Reborn's approach: any protocol that can be expressed as a BICA annotation produces a realizable lattice, and any realizable lattice can be expressed as a BICA annotation.

Lattice-theoretic characterizations. The spirit of our characterization—identifying the image of a construction by an intrinsic property—has a long history in lattice theory. Birkhoff's fundamental theorem of finite distributive lattices [2] characterizes distributive lattices as those isomorphic to downset lattices of finite posets. Grätzer's congruence lattice representation theorem [7] asks which lattices arise as congruence lattices of algebras. Our result is in this tradition, but the "construction" is the session type grammar rather than an algebraic operation, and the "intrinsic property" is reticular form rather than a lattice-theoretic condition like distributivity or modularity.

10 Conclusion

We have established the **Characterization Theorem**: a finite bounded lattice is realizable as a session type state space if and only if it has reticular form. This cleanly answers the inverse problem for session types, closing the loop between syntax (the grammar) and semantics (the lattice).

The theorem provides three practical tools:

- A **decision procedure** for realizability: given any state machine, check whether its reachability poset is a bounded lattice with reticular form. If yes, the reconstruction algorithm produces the session type.
- A **diagnostic framework**: when a state machine is not realizable, the obstruction taxonomy (5 categories, 18 witnesses) pinpoints exactly what goes wrong.
- A **theoretical guarantee**: the session type grammar is neither too weak (it reaches all reticular lattices) nor too strong (it produces only reticular lattices). The grammar and the lattice condition are in perfect correspondence.

The empirical evidence is comprehensive: 79 benchmarks across 7 domains, 478,000+ enumerated types, and 6 wild state machines—all realizable. The Lean 4 mechanization (22 modules, zero sorry) provides machine-checked confidence.

The characterization confirms what the Reticulate Programme has been building towards: session types and bounded lattices with reticular form are two descriptions of the same mathematical object. The grammar generates exactly the lattices that have the right shape, and the lattices that have the right shape are exactly those that the grammar can express.

This duality between syntax and semantics is the hallmark of a mature theory. Just as regular expressions and finite automata describe the same class of languages (Kleene's theorem), and context-free grammars and pushdown automata capture the same computational power (the equivalence theorem), session types and reticular bounded lattices are two views of a single mathematical reality. The Characterization Theorem is, in this sense, the "Kleene's theorem" of session types: it tells us precisely which semantic objects (lattices) correspond to which syntactic objects (session types), completing the circle between grammar and structure.

Future work. Three directions suggest themselves:

1. **Multiparty realizability**: extending the characterization to global types [10], where the question becomes which products of lattices arise from composable collections of local types.
2. **Trace language connection**: linking realizability to the Chomsky classification of the trace language (Step 14 showed that most benchmarks are regular; realizability may constrain the class further).
3. **Non-reticular lattices**: constructing a genuine example of a bounded lattice that is *not* a reticulate—one that satisfies condition (1) but fails condition (2) of the Characterization Theorem—or proving that no such lattice exists (which would simplify the characterization to just "bounded lattice").

11 Frequently Asked Questions

Q1: Why do we need realizability? Isn't the Reticulate Theorem enough? The Reticulate Theorem answers "what do session types produce?" (bounded lattices). Realizability answers the harder inverse: "which bounded lattices come from session types?" This is essential

for tool builders: given an arbitrary state machine (e.g. extracted from legacy code), can we *type* it with a session type? Realizability gives a precise decision procedure.

Q2: Is the characterization effective (decidable)? Yes. For a finite state space with n states and m transitions: (1) lattice check is $O(n^3)$ (SCC quotient + pairwise meet/join), (2) reticular form check is $O(n \cdot m)$ (classify each state). Both are implemented in Reticulate with polynomial-time algorithms.

Q3: Why are Categories C–E subsumed by the lattice check? In our catalogue, every C/D/E example *also* fails the lattice condition (missing meet/join or unbounded). This is not a coincidence: the "interesting" non-realizable cases (lattice but not reticular) require carefully crafted lattices, which we leave to future work. The current catalogue demonstrates that most natural obstructions manifest as lattice failures.

Q4: Can a lattice be a lattice but not have reticular form? In principle, yes: a lattice where some non-bottom state has both branch-like and selection-like transitions that don't decompose as a product. However, such lattices are rare and don't arise from standard protocol patterns. We have not found a natural example.

Q5: What about infinite session types? Our results apply to finite state spaces. Recursive types ($\mu X.\, S$) produce finite state spaces (via SCC quotient), so all well-formed session types are covered. Infinite-state systems (e.g. from unbounded recursion) are outside our scope.

Q6: How does realizability relate to subtyping? Subtyping ($S_1 \leq S_2$) implies an order-embedding $\mathcal{L}(S_2) \hookrightarrow \mathcal{L}(S_1)$. If L_1 and L_2 are both realizable and L_2 embeds in L_1, then the corresponding session types are related by subtyping. Realizability is a prerequisite for this analysis.

Q7: Does the 18-entry catalogue cover all possible obstructions? No — the catalogue is a *witness set*, not an exhaustive enumeration. There are infinitely many non-realizable lattices. The catalogue demonstrates the five obstruction *categories* with small, illustrative examples.

Q8: Why isn't nondeterminism in the session type grammar? Session types model deterministic protocols: from any state, each method name leads to at most one successor. Nondeterminism would mean the same method call could lead to different states, violating protocol predictability. This is why nondeterministic LTSs are non-realizable.

Q9: What is the role of the Lean mechanization? The Lean 4 formalization proves the forward direction (every constructor preserves lattice structure) and the non-realizability witness (Empty has no lattice). This provides machine-checked confidence that the Reticulate Theorem is correct — a prerequisite for the characterization.

Q10: Can I use `check_realizability` on arbitrary state machines? Yes. The function accepts any `StateSpace` object (not just those built from session types). If the input is realizable, it returns the reconstructed session type. If not, it returns diagnostic obstructions explaining why.

Acknowledgments. This work is part of the Reticulate Programme. The Reticulate tool and Lean 4 formalization are open-source at https://github.com/bica-tools/reticulate.
